

# E-NeRF: Neural Radiance Fields from a Moving Event Camera

Simon Klenk<sup>1</sup>, Lukas Koestler<sup>1</sup>, Davide Scaramuzza<sup>2</sup>, Daniel Cremers<sup>1</sup>

**Abstract**—Estimating neural radiance fields (NeRFs) from ideal images has been extensively studied in the computer vision community. Most approaches assume optimal illumination and slow camera motion. These assumptions are often violated in robotic applications, where images contain motion blur and the scene may not have suitable illumination. This can cause significant problems for downstream tasks such as navigation, inspection or visualization of the scene. To alleviate these problems we present E-NeRF, the first method which estimates a volumetric scene representation in the form of a NeRF from a fast-moving event camera. Our method can recover NeRFs during very fast motion and in high dynamic range conditions, where frame-based approaches fail. We show that rendering high-quality frames is possible by only providing an event stream as input. Furthermore, by combining events and frames, we can estimate NeRFs of higher quality than state-of-the-art approaches under severe motion blur. We also show that combining events and frames can overcome failure cases of NeRF estimation in scenarios where only few input views are available, without requiring additional regularization.

## I. INTRODUCTION

Cameras are frequently used in robotic perception, for tasks such as localization, path planning, scene understanding as well as inspection. Furthermore, cameras are ubiquitous in virtual and augmented reality systems, where they are used for ego localization, spatial reasoning and visualizations. These systems require compact and high-quality visual representations of the underlying three-dimensional geometry. Recently, there has been a trend in the computer vision community to study NeRFs as a solution to scene representation and novel view synthesis. NeRFs represent the scene by a multilayer perceptron (MLP) combined with differentiable rendering [1]. They allow for novel view synthesis at unseen viewpoints. Up to this date, NeRFs have mainly been studied on simulated data as well as on high-quality images in the real world [2, 3], which ensure good surrounding light and minimal noise, apart from a few exceptions such as [4, 5].

However, one common problem of real-world images is motion blur, which is caused by fast motion and high exposure times (usually required in low light scenes). During the exposure time interval, each pixel of the moving camera integrates light from different points in the scene, resulting in a mixture of color values. Hence, motion blur is essentially a loss of information which can cause robotic navigation pipelines to fail [6, 7] and severely limit downstream processing, e.g. inspection tasks. Simply reducing the exposure time is often not feasible, since this also reduces the amount of light received on the sensor, and it increases the amount

of noise. Another problem of real-world images from conventional cameras is their limited dynamic range, which can cause bright regions of a scene to appear fully white and dark regions to appear fully black. This is a problem if the affected image areas contain important information such as text.

The event camera [8] is a type of camera which addresses both these shortcomings of real-world conventional cameras. Hence, it can replace and complement frame-based cameras in tasks where high dynamic range (HDR) and fast motion is common. Motivated by this fact, we propose to use an event camera for estimating NeRFs in challenging real-world capturing conditions. The main contributions of this paper are:

- This is the first attempt to tackle NeRF estimation from event cameras during very fast motion.
- Our method can combine the event stream with (color) images. This allows to estimate NeRFs in challenging conditions where frame-based approaches fail or require additional regularization, e.g. under strong motion blur or if only few frame-based views are available.
- We open-source our code and the simulated datasets to foster further research in this area.

## II. RELATED WORK

This work tackles the problem of reconstructing a 3D neural radiance field (NeRF) from a moving event camera. We thus present related work that focuses on reconstructing NeRFs in challenging scenarios, methods that perform 3D reconstruction from event data, and methods that reconstruct frames from event data. We refer interested readers to the excellent resources on neural fields and neural rendering [2, 3], event-based vision [8], and 3D reconstruction [9, Chap. 13].

*a) 3D Scene Reconstruction:* The reconstruction of 3D scenes from a moving RGB camera has traditionally been tackled by methods that produce sparse point clouds [10, 11], depth maps [12], voxel grids [13], and meshes [14]. Recently, NeRFs [1] have gained popularity due to their ability to synthesize high-quality novel views. Usually, the input images to NeRF contain little noise. One exception to this is Deblur-NeRF [4] which can handle blurry input images by modeling the blur formation process. Their method is limited to moderate motion blur, and they only model nonconsistent blur, i.e. they can only recover a NeRF for blur that is caused by irregular (non-straight, non-circular) motion trajectories. RawNeRF [5] can deal with images captured under low light conditions. Their method requires raw images and does not handle motion blur, which makes it applicable only to scenes captured with a temporarily static camera. Overall, none of these methods work for scenes captured by a moving camera

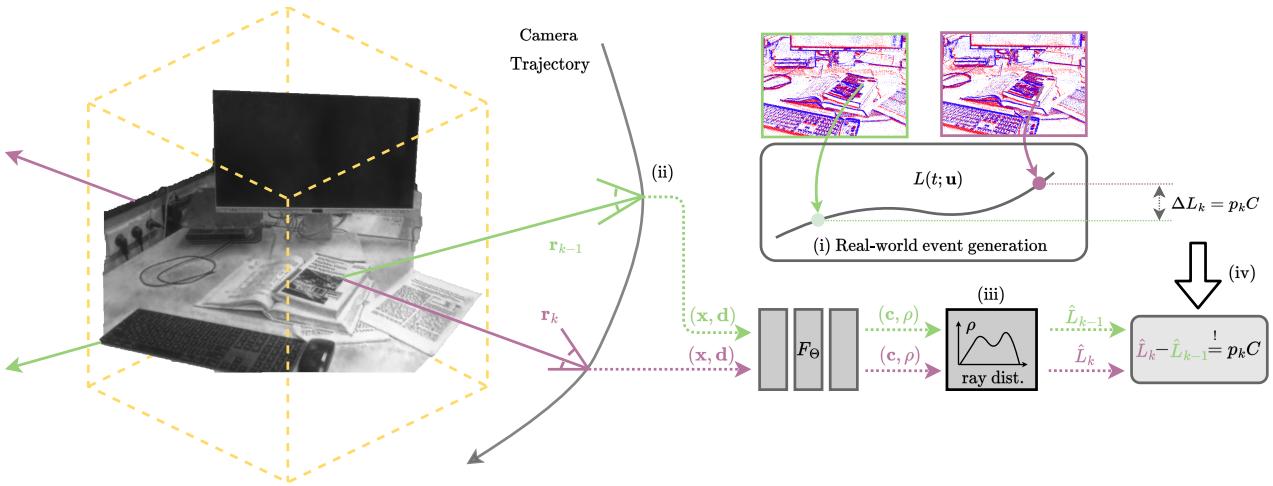

Fig. 1: Overview of the proposed E-NeRF. (i) For a fixed pixel  $\mathbf{u} \in \mathbb{R}^2$  the real-world logarithmic brightness  $L(t; \mathbf{u})$  varies over time. If  $L(t; \mathbf{u})$  crosses a threshold  $C$  wrt. to the memory value a new event is triggered (cf. Eq. 1). (ii) The proposed E-NeRF reconstructs a radiance field from a moving event camera. We evaluate the NeRF-MLP  $F_\Theta$  at the two rays  $\mathbf{r}_{k-1}$  and  $\mathbf{r}_k$  corresponding to the two last events  $e_{k-1}$  and  $e_k$  for pixel  $\mathbf{u}$  to obtain color and density  $(\mathbf{c}, \rho)$ . (iii) The color and density for many points along each ray are accumulated into the final estimated pixel brightness  $\hat{L}_{k-1}$  and  $\hat{L}_k$  using volume rendering. We convert the brightness with the linlog mapping in Eq. 2 to  $\hat{L}_{k-1}$  and  $\hat{L}_k$ . (iv) The event constraint induces the loss function on the two rendered logarithmic brightness values, see Eq. 3 (and Eq. 4 for unknown threshold  $C$ ).

under low light conditions, however, these conditions are common in robotics applications.

*b) Event Cameras:* Event cameras are vision sensors which transmit binary events per pixel, indicating an increase or decrease of the observed logarithmic brightness. Converting this asynchronous data stream to frame-based images is well-studied in 2D [15, 16, 17, 18]. Rebeq et al. [15] train a recurrent U-Net on a paired training dataset of images and synthetic events. They demonstrate intensity reconstruction of high speed phenomena, such as a bullet hitting an object. However, since the event stream does not contain the complete photometric information (it only contains derivative data and is motion-dependent), several approaches combine frames with events. For example, the recent work by Tulyakov et al. [19] trains a fusion network for color frames and events, showing impressive results on the task of frame rate upsampling. Without requiring any training data, the approach by Pan et al. [16] can combine motion-blurred frames with events using energy-based minimization. They model motion blur as an integral over the exposure time, and optimize for a global event contrast threshold. Similarly, the work by Scheerlinck et al. [17] fuses frames with events using a classical filtering technique. Zhou et al. [20] compute a semi-dense 3D reconstruction from event data with known poses, as well as by estimating the poses simultaneously [21, 22]. These works produce a sparse point cloud which represents the geometry of the scene for navigation purposes. In contrast to our work, this point cloud is not well-suited for (novel-view) visualizations.

*c) Concurrent Work:* Rudnev et al. [26] (EventNeRF) and Hwang et al. [27] (Ev-NeRF) investigate how NeRFs could be reconstructed from event data. These works show the need of the event vision community to generate 3D reconstructions from events. The approach by Rudnev et al. aims to reconstruct visually pleasing NeRFs in color space

by using a color event camera. Their setting is constrained to a static event camera with controlled illumination and fully controlled object motion (rotation on a turntable). They assume that events are only triggered by the foreground object, and require the background color to be known. In contrast, we focus on estimating NeRFs from a moving event camera with many background events and under general illumination. The approach by Hwang et al. reconstructs NeRFs from a slowly moving event camera without considering motion blur. In contrast to both of these works, we focus our evaluation on failure cases of frame-based cameras. Additionally, we are the only work to show NeRF reconstructions from a combination of events and frames leveraging the advantages of both sensor modalities.

### III. METHOD

#### A. Optimizing a Neural Radiance Field

Akin to NeRF [1], E-NeRF optimizes a neural radiance field parameterized by an MLP  $F_\Theta : (\mathbf{x}, \mathbf{d}) \rightarrow (\mathbf{c}, \rho)$ , which maps Cartesian input coordinates  $\mathbf{x} \in \mathbb{R}^3$  and viewing direction  $\mathbf{d} \in \mathbb{S}^2$  to the predicted color  $\mathbf{c} \in \mathbb{R}^3$  and volume density  $\rho \in \mathbb{R}$ , see Fig. 1. The predicted color value  $I(\mathbf{u})$  at pixel  $\mathbf{u} \in \mathbb{R}^2$  is obtained by volumetric rendering [28] of  $N$  color predictions  $\{\mathbf{c}_{k,j}\}_{j=1}^{j=N}$  along the ray  $\mathbf{r}_k$ , where  $\mathbf{r}_k = \pi^{-1}(\mathbf{T}(t_k), \mathbf{u}_k, \mathbf{K}, \boldsymbol{\kappa})$ , with interpolated camera poses  $\mathbf{T}(t_k) \in SE(3)$ , pre-calibrated intrinsics  $\mathbf{K}$  and pre-calibrated distortion parameters  $\boldsymbol{\kappa}$ . The original NeRF minimizes a least squares error between the rendered predictions  $\hat{I}(\mathbf{u})$  and ground truth colors  $I(\mathbf{u})$  provided by the images, whereas E-NeRF utilizes the event generation model Eq. 1 to optimize  $F_\Theta$ , which is detailed in the next section. Because ordinary neural networks do not accurately represent high-frequency details, one key implementation detail is to use a proper encoding [29] of input coordinates  $(\mathbf{x}, \mathbf{d})$ . NeRF

TABLE I: SOTA comparison on the spiral sequences. The camera is moving on two different spiral paths (Spiral 1 and Spiral 2) around the synthetic scene, while continuously facing inward to the center of interest. The background texture shows a colored road network (see Fig. 2). The sparse sequences use fewer train views and all sequences show notable motion blur. The proposed E-NeRF shows the best results in the event-only setting as well as when combining events and blurred frames. It shows even better results than NeRF trained on perfectly sharp images, which is partially due to the sparseness of the training views. Deblur-NeRF is often worse than NeRF on the blurred frames because the blur is consistent (cf. Deblur-NeRF paper) and the views are sparse – this reverses for some of the shake sequences in Tab. II. The methods are evaluated on sharp test views using PSNR, SSIM [23], and LPIPS [24]. The best and second-best result are marked in **bold** and underlined, respectively. <sup>†</sup>The “NeRF w/o blur” baseline uses groundtruth sharp frames that would not be available in real-world applications and is thus never marked.

	Spiral 1			Spiral 2			Spiral 1 (sparse)			Spiral 1 (more-sparse)

solves this by applying a Fourier-based feature mapping, whereas E-NeRF use a multi-resolution hash-encoding [30].

### B. Event Stream Utilization

Input to our optimization problem is a continuous stream of events  $e_k = (\mathbf{u}_k, t_k, p_k)$  which occur asynchronously at pixel  $\mathbf{u}_k$  with micro-second timestamp  $t_k$ . The polarity  $p_k \in \{+1, -1\}$  indicates an increase or decrease of the logarithmic brightness  $L(\mathbf{u}_k, t_k)$  by the internal contrast threshold  $C$ , i.e. an event at time  $t_k$  is triggered if the following condition holds:

$$\Delta L = L(\mathbf{u}_k, t_k) - L(\mathbf{u}_k, t_{k-1}) = p_k C \quad (1)$$

where  $t_{k-1}$  is the time of the last event at pixel  $\mathbf{u}_k$  and

$$L(\mathbf{u}, t) = \text{linlog}(I(\mathbf{u})) = \begin{cases} I(\mathbf{u}) \cdot \ln(B)/B, & \text{if } I(\mathbf{u}) < B \\ \ln(I(\mathbf{u})), & \text{else.} \end{cases} \quad (2)$$

The threshold  $B$  determines the linear region, where no logarithmic mapping is applied. Following v2e [31] we set  $B = 20$ , which models realistic event distributions. For each event  $e_k$ , we compute two associated rays  $\mathbf{r}_k$  and  $\mathbf{r}_{k-1}$  at time  $t_k$  and  $t_{k-1}$ , respectively, see Fig. 1. We query the MLP for its color predictions  $\{\mathbf{c}_{k,j}\}_{j=1}^N$  and  $\{\mathbf{c}_{k-1,j}\}_{j=1}^N$  along the respective rays and perform volumetric rendering to obtain  $\hat{I}(\mathbf{u}_k)$  and  $\hat{I}(\mathbf{u}_{k-1})$ . We then perform the linlog mapping in equation 2 to obtain the predicted logarithmic brightness difference  $\Delta \hat{L}_k = \hat{L}(\mathbf{x}_k, t_k) - \hat{L}(\mathbf{x}_k, t_{k-1})$ . Stacking all  $N_{\text{evs}}$  predictions into  $\Delta \hat{\mathbf{L}} \in \mathbb{R}^{N_{\text{evs}}}$  and assuming a Gaussian distribution of residuals  $\Delta \hat{L}_k - \Delta L_k$ , we perform a least squares minimization of the event loss

$$\mathcal{L}_{\text{evs}}(\Theta) = \|\Delta \hat{\mathbf{L}}(\Theta) - \Delta \mathbf{L}(\Theta)\|_2^2, \quad (3)$$

where  $\Delta L_k = p_k C$  is measured by the event camera. The contrast threshold  $C$  of a real event camera varies over the image plane and over time [31], which can make Eq. 1 impractical to use in a real-world setup. Hence, inspired by [22], for real-world data we propose to reformulate the loss to

$$\mathcal{L}_{\text{evs, norm}} = \left\| \frac{\Delta \hat{\mathbf{L}}(\Theta)}{\|\Delta \hat{\mathbf{L}}(\Theta)\|_2} - \frac{\Delta \mathbf{L}(\Theta)}{\|\Delta \mathbf{L}(\Theta)\|_2} \right\|_2^2. \quad (4)$$

### C. Event Sampling

In each optimization step, we include a large number of event pairs from different pixels and at different times. An event pairs consists of an event and its successor event in time (at the same pixel). Our method is general and can also work on event pairs  $\{e_k, e_{k+j}\}$  which are not direct neighbors but further apart in time ( $j > 1$ ). In this case, we accumulate the polarities of all events occurring between the chosen events, i.e. we set the measured brightness difference in our loss function to  $\Delta L_k = C \sum_{i=k+j}^{i=k+j} p_i$ .

Uniform brightness areas do not trigger events. We can include this fact in our model by also sampling from areas where no event has occurred for a time period of  $T_{\text{noevs}}$ . A non-existing event means that the logarithmic brightness did neither increase nor decrease by more than  $C$ , hence we formulate the no-event loss as

$$\mathcal{L}_{\text{noevs}} = \sum_k \text{relu}(|\hat{L}_k - \hat{L}_{k-1}| - C). \quad (5)$$

### D. Implementation Details

We base our code on torch-npg<sup>1</sup> and the training usually converges on one NVIDIA A40 in about 3 hours, using a batch size of up to 40000 rays. Larger batch sizes usually improve PSNR values slightly, and make the model converge faster. Given external poses from a motion capture system, for each sampled event we interpolate the rotational component of its pose  $\mathbf{T}(t_k)$  by spherical linear interpolation (slerp), and the translational component by cubic interpolation.

## IV. EXPERIMENTS

We evaluate the proposed E-NeRF on synthetic data based on ESIM [32] as well as on real-world, public benchmarks. We compare E-NeRF to several baselines: (i) frame-based NeRF [1], (ii) frame-based Deblur-NeRF [4] when considering scenarios with motion blur, and (iii) our novel baseline method consisting of frame reconstruction using E2VID [25] followed by NeRF. E2VID yields strong artefacts during

<sup>1</sup><https://github.com/ashawkey/torch-npg>

fast motion, degrading its performance significantly. For this reason, to be fair to the E2VID baseline, we only feed a subset of all events into E2VID (between 1/4th and 1/16th) during high event rates, and report the best result<sup>2</sup>. While RawNeRF [5] would be a good additional baseline it cannot be used because there was no public code at the time of writing<sup>3</sup> and because it requires raw images from a camera that is static during the exposure. Following the motivation of this work, we consider scenarios that are frequent in robotics and challenging for frame-based (and event-based) vision.

### A. Synthetic Data

We simulate five sequences with different motion trajectories and background textures using the event camera simulator ESIM [32]. Quantitative image metrics are computed between rendered frames and holdout test frames without motion blur. Since the absolute brightness is non-observable from the event stream (see Eq. 1), we perform an affine brightness transform on our predictions using the holdout test frames for all presented methods. The evaluation uses the peak signal to noise ratio (PSNR), the structural similarity (SSIM) [23], and the Learned Perceptual Image Patch Similarity (LPIPS) [24] using AlexNet.

*a) Motion Blur:* We simulate images with motion blur in ESIM by integrating irradiance maps over the exposure time, which yields realistic, motion-dependent blur [32, Sec. 7.4]. Tab. I and Tab. II show that our method produces better results than the baselines. Notably, the results are much better in comparison to combining E2VID with frame-based NeRF. While E2VID has the advantage of being trained on a large dataset, the proposed E-NeRF fuses information in 3D and can leverage spatial consistency without requiring any training data. Additionally, E-NeRF shows better results than frame-based methods, which cannot overcome the strong motion blur. While Deblur-NeRF shows good results for the mild blur in Tab. II, it is worse than vanilla NeRF for the strong blur in Tab. I. This result can be expected because the blur is consistent, i.e. not stemming from random motion in all directions, and the training views are not dense. This shows that carefully modelling the blur process can produce better results, but using blur-resistant event data is preferable. Finally, the results in Fig. 2 show that E-NeRF is able to reconstruct sharp details, which can be beneficial for robotics applications. For example for licence plate detection it is important that the reconstruction is sharp and the characters are legible, while an overall photorealistic reconstruction is less important and potentially infeasible.

*b) Combining Events and Frames:* We show that E-NeRF can combine events and blurry frames to utilize the strengths of both sensor modalities. Using events yields sharp edges but uniform areas show fog-like artefacts due to the discrete nature of events. Additionally, the color for one shaded area might be slightly off because it is never directly

<sup>2</sup>This upsampling is common practice and required for good results, as noted in the [official code](#) of [33].

<sup>3</sup>The [official code](#) was released only four weeks prior to submission of this manuscript and received multiple updates thereafter.

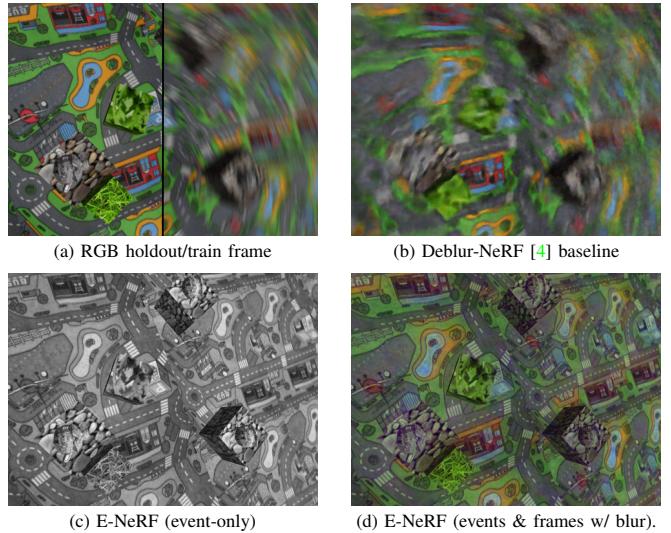

Fig. 2: Qualitative evaluation of sequence Shake Carpet 1. (a) The input views contain strong motion blur. (b) The frame-only baseline Deblur-NeRF [4] can not recover sharp details. (c) In contrast, E-NeRF recovers sharp details from event data only. (d) When combining grayscale events and blurry color frames, our method is able to produce sharp and colored reconstructions. Due to only using grayscale events the colors are not photorealistic, but could still be useful for object recognition.

measured but inferred from derivative-like data. Frame data can help to correct both problems. In Fig. 2 we combine grayscale events and blurry color frames into a sharp and colored reconstruction. We do not require a color event camera but simply map the predicted color value of the event rays to grayscale. Note that most commercially available event cameras are grayscale. Moreover, combining events and frames opens up the potential for low-power reconstruction, where frames are triggered at low-frequency and the event camera captures necessary data in the blind time.

*c) Ablation Study:* We study our method by changing single components and report the average image metrics over all five simulated sequences. Changing the loss function from Eq. 3 to the normalized loss in Eq. 4 results in a minor drop of performance (see line (i) in Tab. III). This is expected, since the normalized loss is an approximation of the ideal physical model. However, the drop in performance is not very large, and we find the normalized loss function to work better on some of the real-world data (e.g. Fig. 4).

Our default sampling strategy is to sample the closest event neighbors in time, which results in an average event pair distance of around 1ms. We investigate a different sampling with event pairs being farther apart in time. To do this, we first divide the event stream into windows of 60ms. For each sampled event, we pick the last event at that pixel in the 60ms window as neighbor, resulting in an average event pair distance of approximately 30ms. We show in line (ii) of table Tab. III that by changing the sampling strategy as described, we receive a minor drop in performance. We believe that this drop might be due to sampling some event rays repeatedly (at the end of the 60ms window). Since this strategy results in unstable training on Shake Moon 1 and Shake Moon 2, we only accumulate up to five events on those sequences.

TABLE II: SOTA comparison on the shake sequences. The camera is performing a random, forward-facing motion with abrupt changes of direction in each sequence. The background textures in the Shake Moon sequences show a gray moon landscape, whereas the background in Shake Carpet 1 consists of a colored road network (see Fig. 2). The proposed E-NeRF shows the best results in the event-only setting and outperforms NeRF trained on blurry frames. Deblur-NeRF is better than NeRF for mild blur, however, not for strong blur in sequence Shake Carpet 1 and not in Tab. I. This shows that modelling the blur process can be beneficial, but using blur-resistant events is preferable and hence E-NeRF shows better results. The methods are evaluated on sharp test views using PSNR, SSIM [23], and LPIPS [24]. The best and second-best result are marked in **bold** and underlined, respectively. <sup>†</sup>The "NeRF w/o blur" baseline uses groundtruth sharp frames that would not be available in real-world applications and is thus never marked.

	Shake Moon 1			Shake Moon 2			Shake Carpet 1		
	train/test views: 39/38, mild blur			train/test views: 33/32, medium blur			train/test views: 20/21, strong blur		
	PSNR $\uparrow$	SSIM $\uparrow$	LPIPS $\downarrow$	PSNR $\uparrow$	SSIM $\uparrow$	LPIPS $\downarrow$	PSNR $\uparrow$	SSIM $\uparrow$	LPIPS $\downarrow$
NeRF [1] w/o blur <sup>†</sup>	33.12	0.93	0.02	28.41	0.84	0.03	29.42	0.87	0.03
NeRF [1] w/ blur	24.22	0.61	0.12	22.04	0.52	0.13	19.69	0.31	0.22
Deblur-NeRF [4]	25.97	0.68	0.20	24.78	0.58	0.36	16.44	0.18	0.69
E2VID [25] + NeRF [1]	22.39	0.80	0.05	22.31	0.78	0.06	22.81	0.80	0.05
E-NeRF event-only	<u>31.10</u>	<u>0.94</u>	<u>0.02</u>	<u>30.32</u>	<u>0.93</u>	<u>0.02</u>	<u>26.65</u>	<b>0.89</b>	<u>0.03</u>
E-NeRF events & blur	<b>31.35</b>	<b>0.95</b>	<b>0.01</b>	<b>30.60</b>	<b>0.93</b>	<b>0.02</b>	<b>27.90</b>	0.89	<b>0.03</b>

TABLE III: Ablation study of E-NeRF. We (i) replace the loss function Eq. 3 by Eq. 4, (ii) change the event sampling from an average event pair distance of 1ms to 30ms, (iii) add the no-event loss from Eq. 5 to the loss function by sampling up to one fourth of no-events in each batch (with  $T_{\text{noevs}} = 25\text{ms}$ ). While those modifications do not improve the average metrics, we find that using them on real data can result in better visual quality. The methods are evaluated using PSNR, SSIM [23], and LPIPS [24]. The best and second-best result are marked in **bold** and underlined, respectively.

	PSNR $\uparrow$	SSIM $\uparrow$	LPIPS $\downarrow$
E-NeRF	<b>28.14</b>	<b>0.88</b>	<b>0.028</b>
(i) normalized loss (Eq. 4)	28.07	0.86	0.031
(ii) event sampling 60ms window	28.13	0.86	0.033
(iii) adding the no-event loss (Eq. 5)	27.76	0.87	<u>0.030</u>

In line (iii) of table Tab. III we show the influence of adding the no-event loss Eq. 5 with a weight of 0.1 to the event loss function. We search for no-events in the time interval  $T_{\text{noevs}} = 25\text{ms}$  and allow up to one fourth of all event rays in the batch to be no-events. This configuration also yields a minor drop in performance. However, we qualitatively find that using the no-event loss can noticeably help to remove artefacts from uniformly colored areas. Moreover, we find that using the no-event loss as well as performing the event accumulation over larger time intervals, can help to improve the visual quality on real data, e.g. in Fig. 3 and Fig. 4.

### B. Real Data

a) **EDS:** We evaluate our method on the public dataset accompanying EDS [22], which uses a beam splitter to capture aligned frames and events from the same viewpoint<sup>4</sup>. We would like to note that for real data, there is no quantitative evaluation possible, since we pick sequences where the frames are severely degraded by motion blur or their low dynamic range. We use sequence 00 to evaluate our method in the dark, as well as sequence 11 to evaluate high speed motion. The selected scenarios are highly challenging for both camera modalities. The darkness in sequence 00 causes high noise levels in both cameras [31]. In sequence 11 the camera is moving at very high speed, which induces strong motion blur in the frames and a very high event rate which

can lead to single events being dropped [34]. For the high-dynamic-range sequence 00 we show the results in Fig. 4. While frame-based NeRF can give decent reconstructions in the bright areas of the scene, it struggles with the dark parts. Both event-based methods, E2VID+NeRF and E-NeRF, show more details of the whole scene. The proposed E-NeRF shows slightly fewer artefacts than E2VID+NeRF especially on foreground objects. For the high-speed sequence 11 we show the results in Fig. 3. Deblur-NeRF provides better reconstructions than frame-based NeRF, but both methods fail to reconstruct sharp details like lettering in the background. E2VID+NeRF and E-NeRF can reconstruct these details and furthermore the proposed E-NeRF reconstructs the geometry of the table, which E2VID+NeRF fails to achieve. Overall, event-based methods are clearly superior for the presented real-world low light and high-speed scenarios. Furthermore, E-NeRF delivers reconstructions with better high-frequency details and better geometry in comparison to E2VID+NeRF. No method achieves photorealistic quality, however, this is not necessary for many robotics applications and might be infeasible due to the difficulty of the tackled scenario.

b) **TUMVIE:** We use the sequence mocap-desk2 to evaluate our method on TUMVIE. The baseline between event and frame camera is about five centimeters in this dataset. The camera follows a forward facing, circular path inducing mild motion blur in the frames. The results in Fig. 5 show that E-NeRF can reconstruct fine details on the book cover and fine-grained text on the paper as well as on the opened book page which is not possible with frame-based NeRF, although the dataset features a high-quality uEye UI-3241LE-M-GL frame camera. We show that by combining events and frames, it is possible to improve the reconstruction in uniformly colored areas, e.g. on the table and on the dark keyboard. We empirically notice that the visual quality of E-NeRF is better on TUMVIE than on EDS. This might be due to the novel event camera model used in TUMVIE (Prophesee Gen4HD compared to Gen3 in EDS), as well as better illumination of the tested scenes. In the second row of Fig. 5 we show that NeRF can not reconstruct correct geometry when we decrease the number of input views to six. By combining the events with those six input views, we can achieve

<sup>4</sup>Since the event and frame camera have different intrinsics parameters (which we use for training and evaluation), the field of view differs slightly in the shown renderings Fig. 4 and Fig. 3.

Fig. 3: Qualitative evaluation on EDS-11 during high speed motion. Holdout frames (a) are not used during optimization. Due to very strong motion blur, the NeRF baseline (b) can not recover proper geometry. The Deblur-NeRF baseline (c) can reconstruct the scene, but shows artefacts on the wall and is missing details such as the eyes of the toy figure or the university logo. The E2VID+NeRF baseline (d) shows good performance on uniformly colored areas, while not being able to reconstruct detailed geometry and texture. Our method (e) can better reconstruct sharp details, such as the lettering, the book cover, the grid structure of the ball, as well as the texture of the boxes in the last row. The E-NeRF result is obtained by picking a fixed threshold of  $C = 0.2$ , and by adding  $\mathcal{L}_{\text{noevs}}$  Eq. 5 with weight one to the loss ( $T_{\text{noevs}} = 30\text{ms}$ ), which improves visual quality on the white background. E2VID uses upsampling of factor 16.

a small improvement on uniform brightness areas compared to the event-only method, while preserving high-frequency details. This is in line with the finding of our train view sparsification experiment of Spiral 1 (Tab. I), where using fewer input views did not degrade E-NeRF (events & frames) by much. E2VID+NeRF can reconstruct uniform color areas on the mocap-desk2 sequence but it does not recover the text.

*c) Discussion:* For challenging real-world scenarios in low light conditions and with fast camera motion E-NeRF clearly outperforms frame-based NeRF. Additionally, E-NeRF often shows clearer details and fewer artefacts than E2VID+NeRF, however, the gap is smaller than for synthetic data. The major reason is that the event generation model of Eq. 1 is only an approximation and less accurate for these challenging scenarios. Switching to a different event camera model generally amounts to changing the loss function, which makes E-NeRF an excellent vehicle for studying event camera models for 3D reconstruction. Ultimately, a model that takes into account all spatial and temporal dependencies might be hard to specify analytically and should be learned from data. We consider this a fruitful direction for future re-

search that could lead to real-world E-NeRF reconstructions that are on-par with reconstructions generated from synthetic data.

## V. CONCLUSIONS

We present E-NeRF, the first method that reconstructs a neural radiance field from a fast-moving event camera. We specifically focus on scenarios that are common in robotics, such as strong motion blur or non-ideal illumination in the dark. We show on synthetic and real-world data that E-NeRF outperforms multiple baselines and ablate our design choices. In particular, we show that E-NeRF is able to better reconstruct high frequency details such as text. We show that if only few input views are provided, an additional event stream helps to estimate NeRFs. Our method can even combine color frames with grayscale events to obtain a sharp, colored reconstruction that utilizes the strengths of both sensors. We see promising future work in the direction of devising better sensor models for event cameras (under challenging capturing conditions), and incorporating learning-based priors.

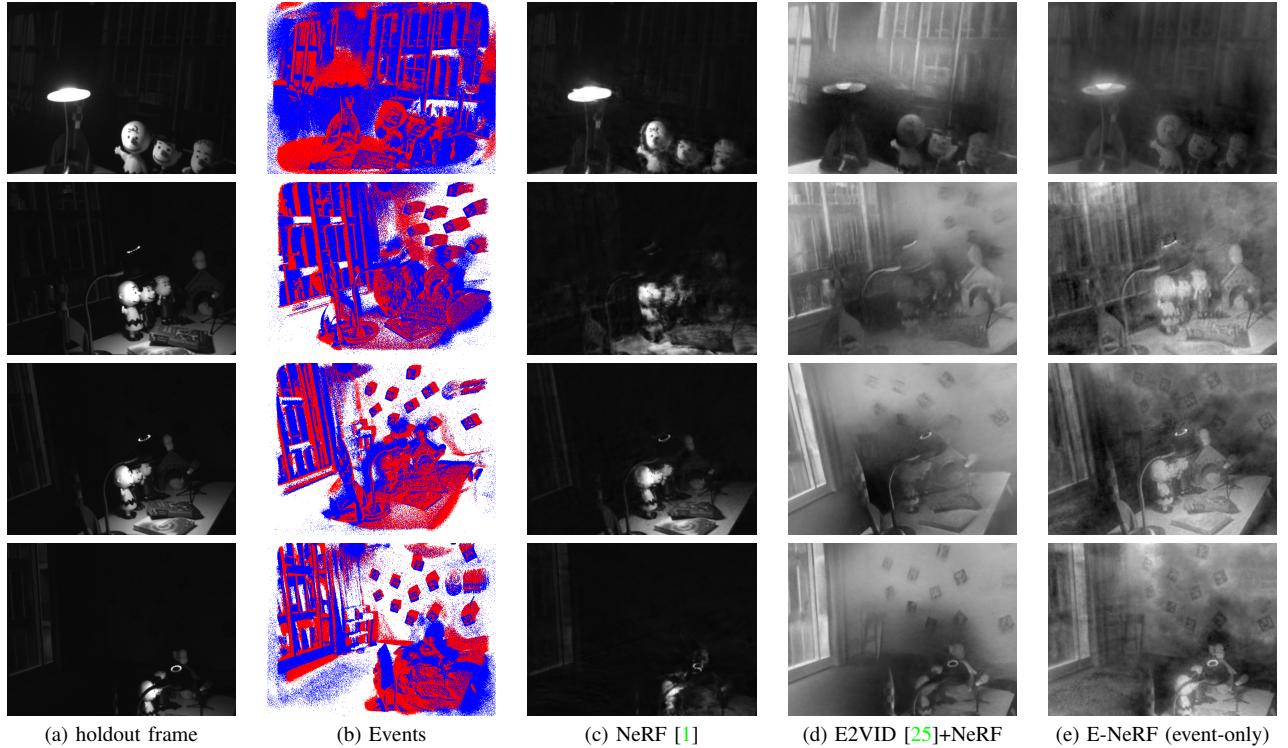

Fig. 4: Qualitative evaluation on EDS-00. We show the holdout frames (a), as well as the closest input events (b) to E2VID (d) and E-NeRF (e). Notice how the NeRF-baseline (c) shows geometry artefacts for some novel viewpoints and can not reconstruct the wall at the back of the room due to limited dynamic range. The E2VID+NeRF (d) baseline can recover details in the dark regions, but shows overly dark reconstructions of the illuminated figures. E-NeRF (e) can reconstruct sharp details in the foreground, such as the book cover and detailed clothing. E-NeRF can even reconstruct the writing on the background wall in the top-right corner of the third and fourth row. The E-NeRF result is obtained by using the normalized loss Eq. 4, adding  $\mathcal{L}_{\text{noevs}}$  Eq. 5 with weight one to the loss ( $T_{\text{noevs}} = 30\text{ms}$ ), and sampling from event windows of up to 130ms. We perform a simple contrast normalization on the E-NeRF renderings for better visual clarity. E2VID uses upsampling of factor of 4.

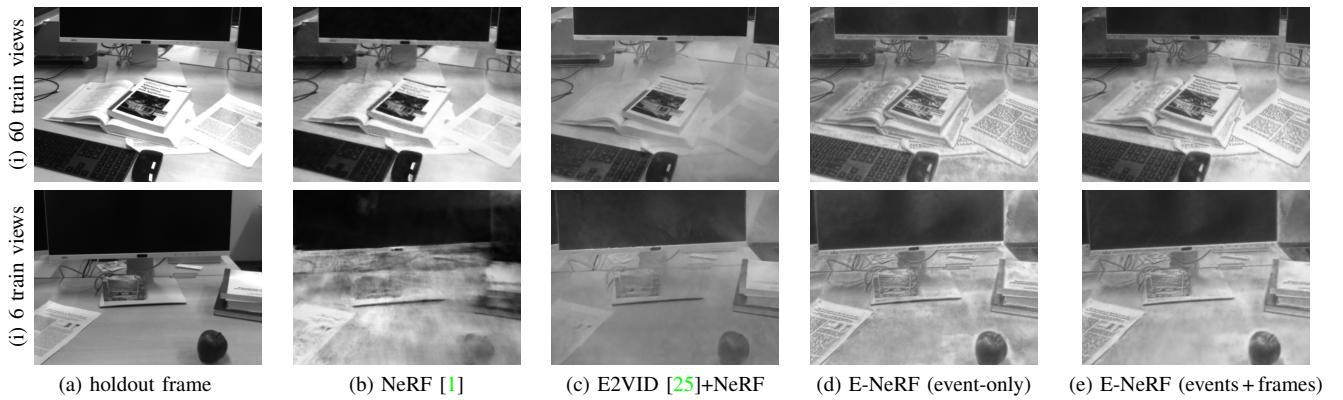

Fig. 5: Qualitative evaluation on TUM-VIE mocap-shake2. We crop the renderings of all methods to highlight the same part of the scene. (i) Due to strong specularities at the table and mild motion blur, the NeRF baseline with 60 train views (b) is not fully sharp and shows artefacts around the book cover and text. E2VID+NeRF (c) can recover more details on the dark keyboard but is not fully sharp and fails to recover text. E-NeRF (d) can reconstruct high-frequency details such as the outline of the book cover and fine-grained text on the papers. Combining events and frames (e) removes artefacts on uniformly colored areas on the table and on white spaces of the book cover and papers, while preserving high frequency details. (ii) By using only six train views, NeRF is not able to reconstruct proper geometry. E2VID+NeRF gives decent reconstructions on the table but fails to capture fine details such as the monitor buttons and text, which E-NeRF can reconstruct properly. Combining the six train views with events (e) improves visual artefacts of E-NeRF in uniform brightness areas, e.g. on the monitor and table. The E-NeRF result is obtained by picking a fixed threshold of  $C = 0.2$ . E2VID uses upsampling of factor of 4.
