**Abstract.** We present an imaging and neural rendering technique that seeks to synthesize videos of light propagating through a scene from novel, moving camera viewpoints. Our approach relies on a new ultrafast imaging setup to capture a first-of-its kind, multi-viewpoint video dataset with picosecond-level temporal resolution. Combined with this dataset, we introduce an efficient neural volume rendering framework based on the *transient field*. This field is defined as a mapping from a 3D point and 2D direction to a high-dimensional, discrete-time signal that represents time-varying radiance at ultrafast timescales. Rendering with transient fields naturally accounts for effects due to the finite speed of light, including viewpoint-dependent appearance changes caused by light propagation delays to the camera. We render a range of complex effects, including scattering, specular reflection, refraction, and diffraction. Additionally, we demonstrate removing viewpoint-dependent propagation delays using a time warping procedure, rendering of relativistic effects, and video synthesis of direct and global components of light transport.

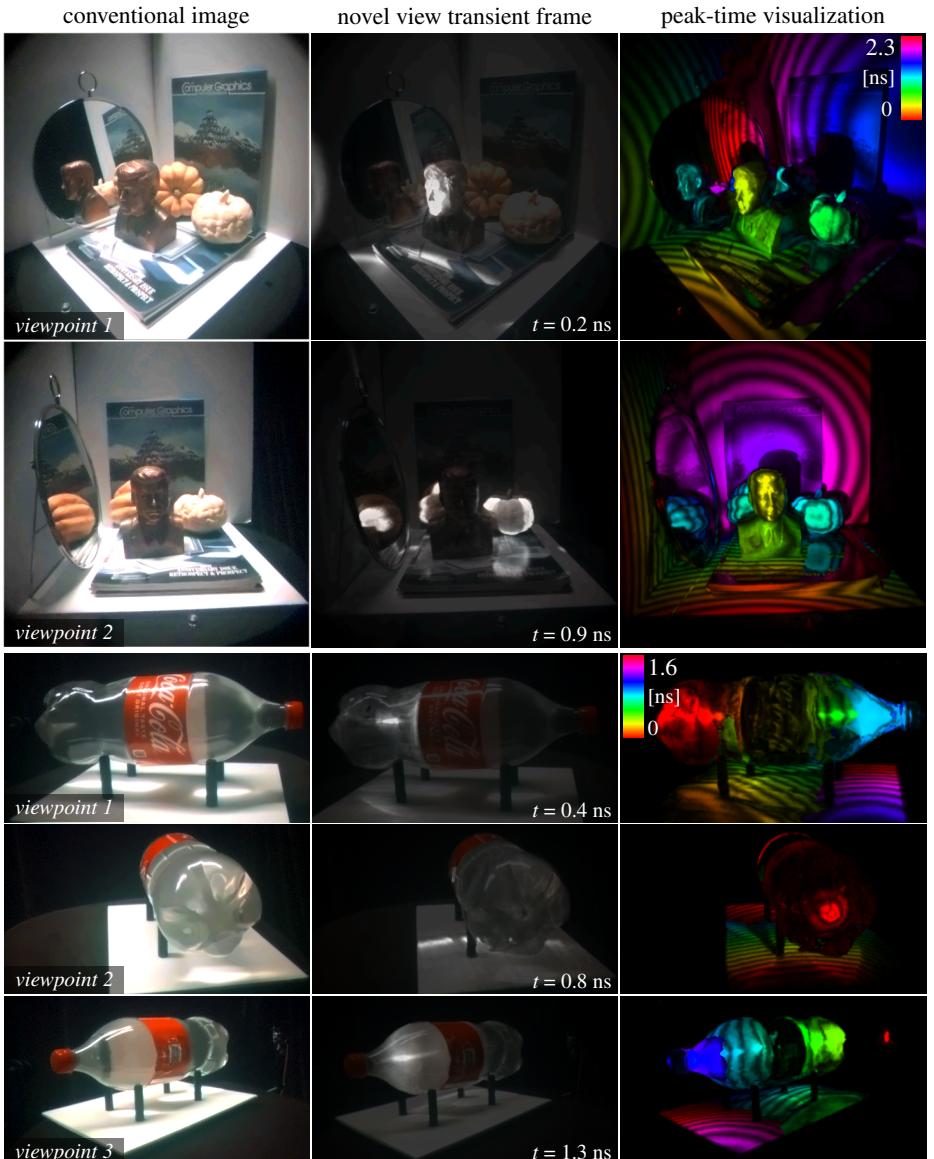

## 1 Introduction

By imaging at trillions of frames per second, ultrafast cameras record videos of propagating light. These *transient videos* reveal the appearance of the world at the speed of light [62]. Such measurements of light transport are useful in a variety of applications: they can be used to understand fundamental mechanisms in physics [29], to recover material properties [40], and to image through living tissue [51] or behind occluders [8]. Our specific aim is to synthesize transient videos from arbitrary, dynamic camera viewpoints (Fig. 1), enabling flexible visualization of light transport and facilitating new applications based on 3D representations of light propagation.

Current state-of-the-art techniques for novel view synthesis use images of a scene captured from multiple viewpoints [60]. However, these techniques are at odds with existing setups for transient videography that are primarily intended for single-viewpoint capture. For example, existing transient video systems use interferometry [1, 13, 25] or pulsed lasers combined with streak cameras [11, 62] or single-photon avalanche diodes (SPADs) [12, 44]. Due to the complexity of these capture setups, multi-viewpoint transient videos have so far been available only in simulation [20], and exploring applications in novel view synthesis has been precluded by a lack of captured datasets.

---

\* anagh@cs.toronto.edu

**Fig. 1: Flying with Photons.** The input to our method is a set of multi-viewpoint transient videos that capture a scene illuminated by a diffused or collimated pulsed light source. We then render videos of propagating light—*transient videos*—from different novel viewpoints at different moments in time. **Left:** Conventional image of the *Kennedy* and *Coke bottle* scenes. **Centre:** Grayscale transient frames rendered from novel viewpoints, composited over the colour image of the scene. **Right:** Adapting the peak-time visualization of Velten et al. [62], we show the entire transient video in a single frame. Hue indicates the time at which the peak intensity is observed at each pixel, and brightness corresponds to the magnitude of the peak intensity. We modulate the brightness over the time dimension to create color bands corresponding to equi-time paths (a.k.a *isochrones*), which reveal the shape of propagating wavefronts.

Applying existing novel view and video synthesis techniques [6, 10, 28, 37, 65] to multi-view transient rendering is not straightforward because they are designed for timescales that are too long for the speed of light to matter. In our setting, the timescale is short enough that the distance between the camera and the scene—and the corresponding speed-of-light time delay—dramatically affects the measurements. Thus, rendering at novel camera–scene distances requires special treatment, and the camera’s velocity can matter as well (e.g., inducing relativistic effects [21]).

Our approach models the finite speed of light and synthesizes transient videos from dynamic (or static) novel viewpoints. We demonstrate the approach using a first-of-its-kind dataset of multi-viewpoint transient videos, captured with a gantry that enables precise azimuth and elevation control of a scanning, single-pixel SPAD (i.e., on the hemisphere surrounding a scene). The SPAD records photon arrivals with picosecond-level accuracy, and is synchronized to a diffused or collimated illumination source that is stationary with respect to the scene and emits picosecond-scale pulses at megahertz rates.

To render transient videos from novel viewpoints, we introduce a volumetric representation that is optimized based on multiple input transient videos, each captured with a static camera from a different viewpoint. Although we consider rendering at speed-of-light timescales, the static cameras of our dataset do not capture relativistic effects—we consider simulating these effects separately as an extension of our method (Sec. 5.3).

Our transient rendering procedure adapts a neural representation [26, 39] to learn two fields—a conventional density field [37] and *transient field*: a mapping from a 3D point and 2D direction to a high-dimensional, discrete-time signal that represents time-varying radiance at ultrafast timescales. After learning these fields, we sample the transient field and density field at points along a camera ray and apply volume rendering to these samples to obtain the synthesized transient waveform at a camera pixel.

Our rendering procedure also accounts for light propagation delays to each camera’s centre of projection. Specifically, we apply a “time unwarping” procedure similar to Velten et al. [62]; applied in our context, it allows us to learn a canonical spacetime representation of the scene, which can then be time-warped to account for propagation delays to any camera viewpoint.

In summary, we provide the following contributions.

- We render light propagating through real scenes from novel, moving viewpoints for the first time.
- We introduce a transient field representation to make this possible and evaluate our method on a range of scenes with inter-reflections, multiple scattering, refraction, and diffraction.
- We build a system for multi-viewpoint transient videography and capture a dataset of scenes with complex light transport effects.
- We show additional capabilities, including time unwarping, relativistic rendering, and direct-global separation of light transport.

## 2 Related Work

*Capturing light transport.* Our work is closely related to time-resolved imaging modalities that directly capture light in flight [30, 44, 62]. Among these modalities, interferometry provides the highest temporal resolution and resolves light propagation at micron scales [13, 25]. Still, interferometric techniques typically require bulky optical setups and have a limited working range, and so are more suited to microscopic imaging. Streak cameras achieve sub-picosecond resolution [66], but are also bulky and expensive, making them more difficult to use. On the other hand, photonic mixer devices are far less expensive and can be used to reconstruct transient videos, though at coarser, nanosecond scales [15, 45]. SPADs provide a middle ground between these sensing modalities, as they are relatively inexpensive, yet have high temporal resolution at the picosecond level [52]. Our work uses a scanned, single-pixel SPAD with  $\approx 50$  ps temporal resolution.

Various other methods have been developed to capture phenomena relating to light transport. For example, structured illumination can separate light into different components (e.g., direct or indirect) by projecting high frequency patterns [14, 41], illuminating and imaging based on epipolar lines [43, 46], or using a combination of structured illumination and masking [47]. Other work captures light paths directly by imaging scenes placed into a fluorescent medium [16]. However, none of these techniques can capture propagating light.

*Transient rendering.* Transient renderers model light transport effects that arise from the finite speed of light [19, 57]. They account for propagation delays between light sources and surfaces in the scene [50, 54], as well as effects due to refraction [2], scattering [18], birefringence [19], or volume absorption and scattering [49]. Differentiable transient renderers optimize scene parameters using transient measurements [70, 71]. While they have shown promise for non-line-of-sight imaging [17, 61], scaling these techniques to multi-view captures of complex scenes remains a challenge.

At transient timescales, camera motion induces relativistic effects, including time dilation, distortions that arise from the contraction of spacetime (Lorentz contraction), Doppler shifts, and the searchlight effect [21, 68, 69]. Our dataset does not capture relativistic effects because the camera is static during capture. Thus, our primary aim is not to achieve physically accurate rendering of such effects; however, we do include a limited extension to our approach that simulates certain relativistic effects, inspired by the method of Jarabo et al. [21].

Similar to us, Jarabo et al. [21] also explore rendering transient videos from novel viewpoints. However, their approach uses a single-viewpoint transient video for which the scene geometry is known. They extract a textured mesh by projecting the transient video appearance onto the scene geometry, and this enables re-rendering from any viewpoint. Our approach is significantly more general as we jointly optimize for geometry and the view-dependent appearance of transient videos, and we incorporate data from multiple viewpoints.

We are also inspired by Velten et al. [62]; we use a similar style of peak-time visualization (shown in Fig. 1), and we extend their time warping procedure to

model propagation delays in our volume rendering framework. In their approach, time warping was used to remove the scene–camera path length in a single-viewpoint transient video. In our work, time warping appears as a propagation delay that we add to samples of the transient field along a camera ray. We also demonstrate using time warping to remove scene–camera path lengths in transient videos rendered with dynamic cameras, which removes view-dependent propagation delays and makes the visualization more intuitive.

*Neural rendering.* Our work builds on methods for 3D reconstruction and novel view synthesis based on neural radiance fields (NeRFs) [37]. While such techniques have been developed to, e.g., model refractive objects [3, 48, 72] and glossy surfaces [63], or to perform inverse rendering tasks [22, 24, 33, 38, 56, 58, 64, 74], no previous method performs novel view synthesis of complex, time-resolved light transport effects observed from multiple viewpoints. To do so requires a dataset that captures these effects and a representation to facilitate rendering them. Neither of which are currently available; our method provides both.

Closest to our work is TransientNeRF [34], which performs novel view synthesis of the direct component of transient measurements i.e. from the data used in lidar. However, TransientNeRF cannot render indirect light transport effects, and relies on a lidar-specific image formation model, where the sensor and light source are coaxial. In contrast our approach can handle a non-coaxial light source, such as a point source or collimated beam placed anywhere within a scene. Further, we can render more general light transport effects, such as diffuse and specular reflections, multiple scattering, refraction, and diffraction.

## 3 Rendering Propagating Light with Transient Fields

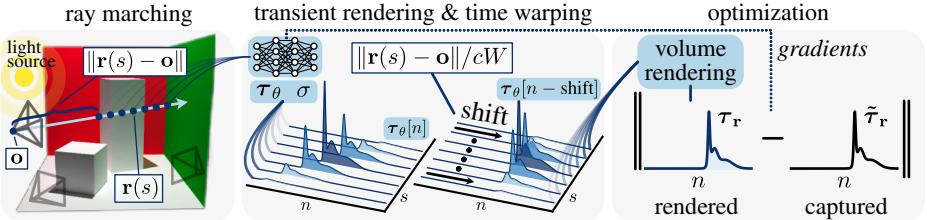

### 3.1 SPAD Measurement Model

Consider a scene that is illuminated by an ultrashort pulse of light from a stationary laser source that is diffused or collimated. The wavefront of this impulse interacts with the scene through a potentially complex sequence of events, including reflection, refraction, or scattering before being reflected back to a camera pixel along a ray  $\mathbf{r}$ . We model the time-varying photon radiance of light along  $\mathbf{r}$  as the impulse response of the scene  $h(\mathbf{r}, t)$ . Then, the expected number of photons  $\lambda_{\mathbf{r}}$  collected by an ideal detector during a time bin of width  $W$  is proportional to the integral of photon radiance over time:  $\lambda_{\mathbf{r}}[n] \propto \int_{nW}^{(n+1)W} h(\mathbf{r}, t) dt$ .

In practice, we use a single-photon avalanche diode (SPAD) to count the number of photons detected within each time bin, resulting in the measured transient  $\tilde{\tau}_{\mathbf{r}}$ . The photon detections are distributed according to an inhomogeneous Poisson process whose time-varying rate function is  $\lambda_{\mathbf{r}}$  [53]:

$$\tilde{\tau}_{\mathbf{r}}[n] \sim \text{POISSON}(P\eta\lambda_{\mathbf{r}}[n] + B), \quad B = P(\eta A_{\mathbf{r}} + D). \quad (1)$$

Here,  $P$  represents the number of laser pulse periods used to capture measurements,  $\eta$  is the detection efficiency of the SPAD, and  $B$  is the expected number

**Fig. 2:** We cast a ray into the scene and query a neural representation at samples  $\mathbf{r}(s)$  along the ray to retrieve an  $N$ -dimensional transient  $\tau_\theta$  and density value  $\sigma$  for each sample. Each element  $\tau_\theta[n]$  of that transient corresponds to a time bin of width  $W$  times the speed of light  $c$ . We time-shift each transient based on the time delay from the camera origin  $\mathbf{o}$  to  $\mathbf{r}(s)$  and composite them together using volume rendering. The neural representation parameters are optimized to minimize the difference between the rendered transient  $\tau_r$  and the captured transient  $\tilde{\tau}_r$ .

of photons due to ambient light  $A_r$  and the dark count rate  $D$  of the sensor. Although SPADs exhibit other second-order effects, such as dead time, afterpulsing, or cross-talk [5], these can be neglected in the low-flux regime considered in this work, where less than 5% of emitted laser pulses lead to a photon detection [42]. Increasing the number of laser pulses results in improved signal-to-noise ratio and measurements that better approximate the photon arrival rate.

### 3.2 Transient Fields and Rendering

We use a volumetric representation of the scene to render the transient  $\tau_r \in \mathbb{R}_+^N$  given a camera ray  $\mathbf{r}$  (see Fig. 2). Specifically, we define a point on a ray  $\mathbf{r}(s) = \mathbf{o} + s\mathbf{d}$  where  $\mathbf{o} \in \mathbb{R}^3$  is the camera center of projection and  $\mathbf{d}$  is a three-dimensional unit vector corresponding to the ray direction. The transient field,  $\tau_\theta : (\mathbf{r}(s), \mathbf{d}) \mapsto \mathbb{R}_+^N$ , is a neural representation with parameters  $\theta$  that maps a three-dimensional point and a ray direction to the discrete time bin values of a transient. Additionally, the neural representation outputs a spatially varying absorption coefficient  $\sigma(\mathbf{r}(s))$ , which gives the differential probability of ray termination at each point in the volume. Finally, the transient along ray  $\mathbf{r}$  is computed using a modified version of the volume rendering equation:

$$\tau_r = \int_{s_n}^{s_f} T(s)\sigma(\mathbf{r}(s)) \left[ \tau_\theta(\mathbf{r}(s), \mathbf{d}) * \underbrace{\delta[n - \|\mathbf{r}(s) - \mathbf{o}\|/(cW)]}_{\text{propagation delay}} \right] ds,$$

where  $T(s) = \exp\left(-\int_{s_n}^s \sigma(\mathbf{r}(u)) du\right)$ . (2)

Here,  $T$  represents transmittance from ray distance  $s_n$  to  $s$ , and  $c$  is the speed of light. The transient vectors  $\tau_\theta$  sampled along the ray are time shifted via convolution (\*) with the Kronecker delta function  $\delta$ —this accounts for the propagation delay to the camera and is similar to the time warping procedure of Velten et al. [62]. If the time shift is not modeled, there is an ambiguous mapping from

$(\mathbf{r}(s), \mathbf{d})$  to shifted versions of the same transient, depending on the distance to the camera center of projection. The volume rendering integral is evaluated numerically using the quadrature rule proposed by Max [36].

### 3.3 Implementation Details

*Optimization procedure.* We optimize the transient field representation  $\tau_\theta$  using SPAD measurements  $\tilde{\tau}_{\mathbf{r}}^{(v)}$  captured from  $0 \leq v \leq V - 1$  different viewpoints. The neural representation is optimized using the loss function

$$\mathcal{L} = \sum_{v, \mathbf{r}, n} \|g(\tilde{\tau}_{\mathbf{r}}^{(v)}[n]) - \tau_{\mathbf{r}}^{(v)}[n]\|_2^2, \quad (3)$$

where the summation is over all viewpoints, camera rays, and transient time bins. Since the measured transients can have a high dynamic range (e.g., spanning zero to thousands of photons), we apply a gamma function,  $g(x) = x^{1/\gamma}$ , to compress the dynamic range and to improve the ability of the neural representation to fit weak signals, such as multiply scattered light.

We parameterize  $\tau_\theta$  using an adapted version of the NerfAcc [27] implementation of Instant-NGP [39] (see supplement). The model is trained using the Adam optimizer [23] until convergence, which typically occurs after 500k iterations for the simulated dataset and 1M iterations for the captured dataset. During training, we anneal the learning rate after 50%, 75%, and 90% of the training iterations by a factor of 0.33. Training requires roughly 10 hours for the simulated scenes and 20 hours for the captured scenes due to the higher temporal resolution of transient in the captured data. We select the batch size to fit within 48 GB of VRAM on an NVIDIA A40 GPU. We use  $\gamma = 5$  for simulated measurements and  $\gamma = 2$  for captured measurements, which we set empirically to balance contrast and detail in the rendered transient videos. To render color transients for the simulated dataset, we modify the transient field such that  $\tau_\theta : (\mathbf{r}(s), \mathbf{d}) \mapsto \mathbb{R}_+^{3N}$ , i.e., it outputs a separate transient for each color channel. We assume that the camera intrinsics and extrinsics are known, and we describe our calibration procedure in the following section.

*Dynamic viewpoint rendering.* After training, the same rendering procedure can be used to create transient videos of a scene from a dynamic camera viewpoint. This is accomplished by defining a time-varying camera trajectory consisting of camera extrinsics,  $[\mathbf{R}_n | \mathbf{t}_n]$  (i.e., rotation and translation), corresponding to every transient time bin  $\tau_{\mathbf{r}}[n]$ . The  $n$ th frame in the output transient video is rendered by computing  $\tau_{\mathbf{r}}[n]$  for the camera rays transformed by the extrinsics.

## 4 Multi-Viewpoint Transient Dataset

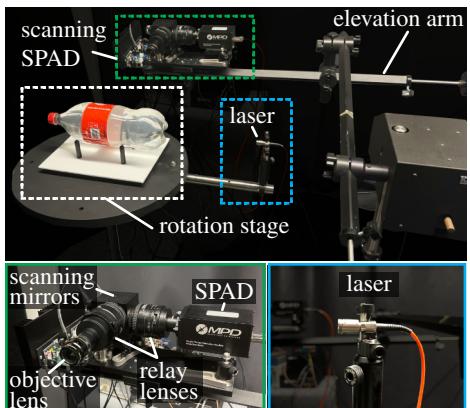

*Simulated dataset.* We use the renderer of Liu et al. [31] as well as a version of Mitsuba 2 modified for transient rendering [54] to simulate transient videos from multiple viewpoints. The illumination is a point source that emits a temporal

impulse into the scene. For the Mitsuba 2 scenes we move the camera to sample a grid of 31 by 3 viewpoints on a hemisphere spanning 45 to 180 degrees in azimuth and 30 to 45 degrees in elevation. We create a total of 4 synthetic scenes based on the Cornell box or assets from Blendswap (<https://blendswap.com/>) and Bitterli [4], which we assemble together in Blender [59]. To evaluate the method, we render a set of 30 unseen viewpoints sampled on the same hemisphere as the training views, which is consistent with what we capture using our hardware system. We also capture another set of 30 unseen viewpoints that extend beyond the training views by sampling on a hemisphere of radius roughly 20% greater than the training one. The simulated transients are rendered at 512x512 resolution and the number of time bins ranges from 300 to 900 depending on the scene scale.

*Hardware prototype.* We capture a multi-viewpoint transient video dataset using a prototype system (Fig. 3) comprising a single-pixel SPAD, a 2D scanning galvonometer, a set of relay lenses, and an objective lens. The SPAD is synchronized to a 532 nm laser that emits 35 ps pulses of light at a 10 MHz repetition rate. A time-correlated single-photon counter time stamps photon arrivals with a system resolution of approximately 70 ps, and the scanning galvonometer is configured to raster scan the scene at  $512 \times 512$  resolution. We couple the free-space laser beam into a multi-mode fiber and set the output power to keep the incident photon flux to roughly 500k counts per second on average, low enough to avoid pileup.

The camera gantry consists of a rotation stage and an elevation arm on which we mount the SPAD and scanning system. The emission end of the multi-mode fiber and captured scene are mounted on the rotation stage so that the illumination source and scene move together. To capture a conventional color image of the scene with our system, we turn the room lights on and perform sequential captures with red, green, and blue color filters placed in front of the objective lens.

*Calibration and captured dataset.* The camera intrinsics are calibrated by capturing a sequence of intensity images of a checkerboard and using the MATLAB camera calibration toolbox [35, 75]. To calibrate the extrinsics, we place a textured scene and checkerboard on the rotation stage and capture an image from each viewpoint used to capture transient videos. We use COLMAP [55] to solve for the extrinsics, and we scale the resulting camera translations so that the

**Fig. 3:** Multi-viewpoint capture setup. A gantry controls the elevation angle of a scanning SPAD, and a scene and laser source are rotated together on a stage.

**Table 1:** Evaluation of transient rendering from novel viewpoints. We report parameters and time to render a transient video (NVIDIA A6000).

	method	param.	time	PSNR (dB)↑	LPIPS↓	SSIM↑	T-IOU↑

<i>captured</i>	K-Planes [10]	43M	37min	24.115	0.516	0.594	0.395
	(w/o prop. delay)	15M	5.78s	17.118	0.529	0.346	0.174
	proposed	15M	28.0s	24.949	0.431	0.666	0.468

reconstructed size of the checkerboard squares matches the known geometry. We use the same camera intrinsics and extrinsics for all captured scenes.

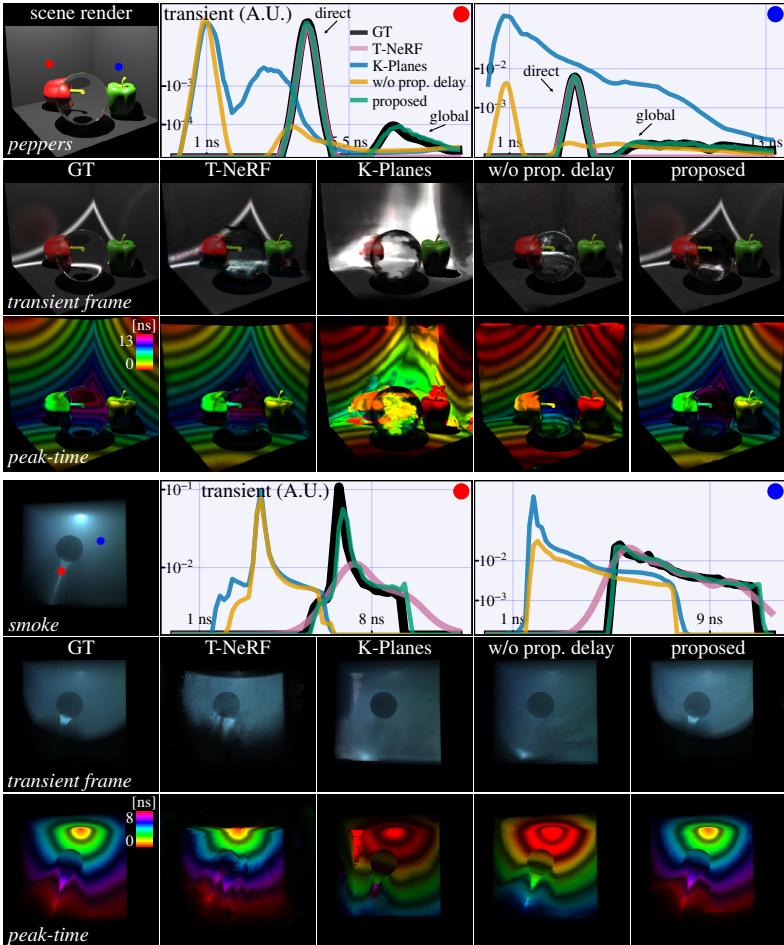

The captured dataset consists of 5 scenes, and for each scene we capture 45 (or 75) transient videos on a grid of 15 (or 25) by 3 viewpoints spanning 125 to 360 degrees in azimuth and 15 degrees in elevation. Capturing each transient video requires 20 to 30 minutes; we bin all captured photons into a transient histogram with 4096 bins, each spanning 4 ps. See the supplement for a detailed description of capture parameters and measured photon counts for each scene. Prior to using the simulated and captured datasets for view synthesis with our method, we normalize them as described in the supplement to ensure that the dynamic range is compatible with the output range of the neural representation. We will make all code and datasets publicly available upon publication.

## 5 Results

We evaluate the proposed method for rendering propagating light from novel viewpoints in simulation and using captured datasets. We compare to baselines, including a modified version of Transient NeRF (T-NeRF) [34]; while this method is intended for lidar view synthesis, we adapt its ray marching scheme to handle the non-coaxial point light source and camera used in our simulated scenes (detailed in the supplement). However, we omit T-NeRF from our evaluation on captured data because it requires the light source position (which we do not calibrate), and we show that it cannot model global effects in the simulated results. We also compare to K-Planes [10], a method for video novel view synthesis that uses a spatiotemporal feature grid and a volume rendering model. Finally, we compare two versions of the proposed method, one with and one without explicitly modeling the propagation delay to the camera (Eq. 2).

### 5.1 Simulated Transient Rendering

We evaluate the approach in simulation on four different scenes: *pots*, *peppers*, *Cornell box*, and *smoke*. We render all scenes using a modified version of Mitsuba 2 [54], except for *smoke*, for which we use the method of Liu et al. [31] because

**Fig. 4:** Simulated results rendered from novel viewpoints for the *peppers* and *smoke* scenes. **Rows 1, 4:** The ground-truth integrated transient is shown alongside transient plots for all methods. The proposed method more accurately represents both the direct and global components of light. **Rows 2, 5:** For all methods, we show one frame of the transient video, composited over the integrated image of the scene. **Rows 3, 6:** Peak-time visualization illustrating the transient in a single frame. Hue encodes the time of peak intensity, brightness is modulated by the maximum intensity, and each band corresponds to an isochrone, or wavefront of equal path length.

it supports rendering participating media. We show rendered novel views and transients on held-out camera viewpoints for the proposed method and baselines in Fig. 4. The proposed method outperforms the baselines in terms of accuracy and computational efficiency. Since T-NeRF cannot model indirect effects, it only recovers the direct component of light transport. K-Planes models time-varying illumination, but does not account for propagation delays to different camera viewpoints (Eq. 2), and so fails to learn the view-dependent shifts in

the time-varying illumination. We observe a similar performance degradation in the proposed method without propagation delay modeling; thus, accurate propagation delay modeling is key to accurate view synthesis for this task.

We report image quality and accuracy of synthesized transients from held-out camera viewpoints, averaged across all scenes, in Table 1. Prior to evaluating our method, we undo the gamma correction learned during training (Eq. 3). To evaluate image quality, we average the rendered transient videos over the time dimension, normalize, gamma correct ( $\gamma = 2.2$ ), and compute PSNR, LPIPS [73], and SSIM [67]. We assess the quality of synthesized transients by introducing a transient intersection over union (IoU) metric. This is calculated as

$$\text{IoU}(\tau_1, \tau_2) = \frac{\sum_n \min(\tau_1[n], \tau_2[n])}{\sum_n \max(\tau_1[n], \tau_2[n])}, \quad (4)$$

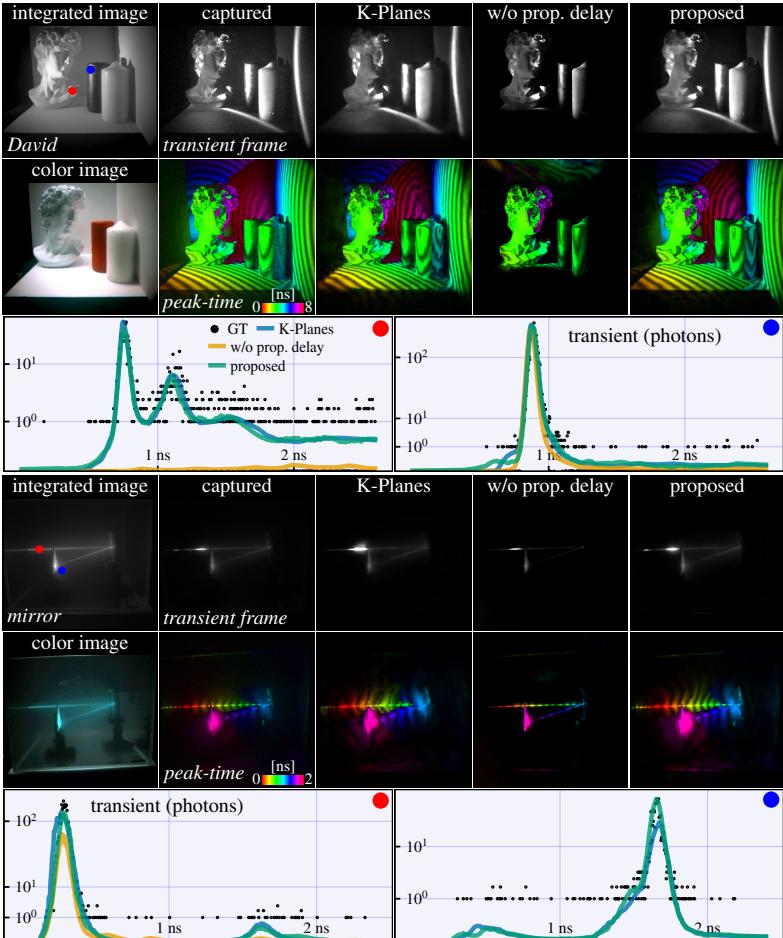

and we report the average transient IoU across all scenes. See the supplement for implementation details of the metrics and for the individual scene metrics.

To evaluate computational efficiency, we measure the time it takes for each method to render a transient video from a single viewpoint; we also report the number of parameters in each model (see Table 1). For this test, we use an NVIDIA A6000 GPU and set the batch size for each method to use the maximum 48 GB of VRAM. K-Planes requires roughly  $25\times$  longer than both T-NeRF and the proposed method because each time bin requires its own rendering pass.

## 5.2 Transient Rendering with Captured Data

We capture five different scenes to evaluate our method and compare with baseline approaches. The *Coke bottle* scene is shown in Fig. 1 and is similar to the result shown by Velten et al. [62], except we perform multi-viewpoint reconstruction. We use a collimated beam to illuminate a Coca-Cola bottle filled with water and a small amount of milk. To illuminate the *Kennedy* (Fig. 1) and *David* (Fig. 5) scenes, we pass the laser through a diffuser; these scenes contain indirect diffuse reflections and the *Kennedy* scene includes a mirror reflection. Finally, the *mirror* and *diffraction* (see supplement) scenes are captured by illuminating a tank of water and milk with a collimated beam. In the *water* scene the light passes through a mirror and is directed to a diffuse target. The *diffraction* scene captures a collimated beam passing through a diffraction grating.

Overall, we observe similar trends for captured transient novel view synthesis as in simulated data. However, because the captured data uses roughly  $4\times$  the number of histogram bins as simulated data (for finer the temporal resolution), we find that we need to increase the number of parameters in the K-planes model to reliably fit the data. Due to the increased parameter count the performance of K-Planes improves upon the proposed method without modeling the propagation delay. However, this improvement comes at the cost of longer inference times, where K-Planes takes  $80\times$  longer to render a single transient video than the proposed method (see Table 1). Qualitatively, the proposed method recovers more plausible videos with fewer artifacts compared to the baselines (Fig. 5). The

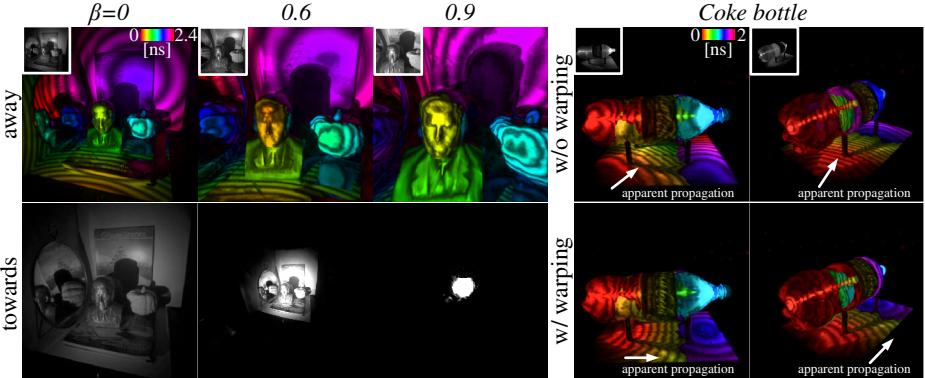

**Fig. 5:** Captured results rendered from novel viewpoints for the *David* and *mirror* scenes. **Row 1, 4:** For all methods, we show one frame of the transient video, composited over the integrated image of the scene. **Row 2, 5:** Peak-time visualization. **Row 3, 6:** Transient plots. We show the captured photon count using a scatter plot instead of a continuous line, due to the sparse and quantized nature of the measurements. The methods reconstruct a continuous approximation of the underlying transient and suppress the noise observed in the captured data.

approach also outperforms the baselines in terms of image quality and transient IoU (Table 1). See the supplement for additional results and videos.

### 5.3 Applications

*Time warping.* Our approach can be used to visualize light transport in different ways through time warping, which involves adding or removing time delays to the rendered transients. For example, following Velten et. al [62] we can perform depth-based time warping, which removes the propagation delay from the scene

**Fig. 6:** Relativistic rendering and time warping. **Left:** We render relativistic effects due to motion towards and away from the scene at a fraction  $\beta$  of the speed of light. Lorentz contraction [32] causes objects to appear larger even though the camera moves away from them (top). Approaching the scene at a significant fraction of the speed of light results in increased brightness and shrinkage, resulting in the searchlight effect [21] (bottom). **Right:** Peak-time visualizations for the *Coke bottle* scene with and without depth-based warping. Transient appearance is consistent across viewpoints with depth-based warping.

point to the camera. In the visualization with depth-based warping, points along each camera ray “light up” as soon as they intersect a wavefront of light; in other words, each camera ray is rendered in a different spacetime coordinate frame.

To create this visualization, we calculate the propagation delay to each scene point using the expected ray termination distance [7], and we shift the rendered transient by the corresponding speed-of-light time delay. We compare transients rendered with and without depth-based warping in Fig. 6. Here, the hue of the visualization indicates the time of peak intensity at each pixel (typically corresponding to the direct component of light). The brightness is scaled by the maximum pixel intensity, and we modulate the brightness over the time dimension to add black bands corresponding to isochrones (wavefronts with equal path length). The appearance of the depth-warped transient is consistent across viewpoints, providing a more intuitive visualization.

Our representation enables more general time warping techniques, wherein we shift the transients based on the distance to arbitrary reference surfaces (e.g., defined by a sphere, cube, etc.). We explore extensions to time warping and associated novel visualization techniques in more detail in the supplement.

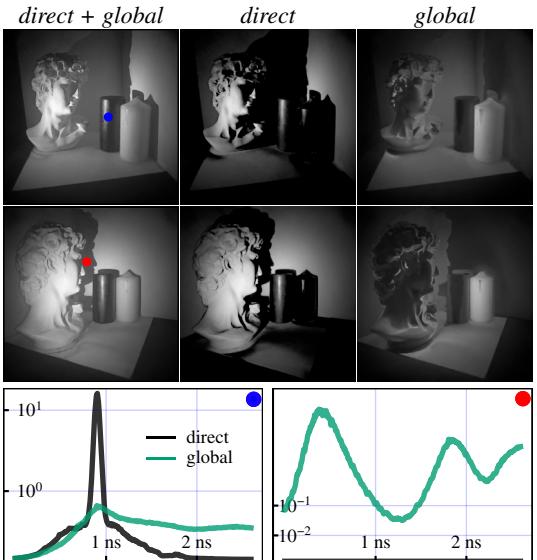

*Relativistic rendering.* We consider rendering scene appearance from a camera moving at relativistic speeds. Rendering such effects has been explored in previous work [21, 69] and we adapt these techniques into our transient rendering framework. As an observer approaches the speed of light, different effects alter scene appearance as shown in Fig. 6. Specifically, we model (1) time dilation between the moving inertial frame of the camera and the static scene; (2) deformation of the camera focal length due to Lorentz contraction [9, 32]; (3) light aberration, which causes light rays to curve and compress towards the direction

of motion; and (4) the searchlight effect, which describes the increase in photon flux for a camera traveling at relativistic speeds towards an illumination source. We provide implementation details and additional results in the supplement.

*Direct–global separation.* We show how our method can be used for 3D visualization of direct and global components of light transport. First, we pre-process the captured transient data to separate direct and global components by fitting a Gaussian mixture model to each transient. To identify the direct component, we check if the Gaussian closest to time zero matches the expected profile of the laser impulse used to illuminate the scene. We model the global component using the remaining Gaussians (see the supplement for a detailed description of this procedure). Finally, we train separate instances of our model on the direct and global components, allowing us to synthesize the corresponding direct and global transient videos (see Fig. 7).

## 6 Discussion

Our work introduces a method for *flying with photons*: rendering propagating light from novel, moving camera viewpoints. We envision many avenues for potential impact based on our technique, including in applications related to education, art, or for scientific observations of ultrafast phenomena that have so far been limited to capture from a single viewpoint. While the main focus of this work is on rendering and visualizing transient phenomena, multi-viewpoint transient videos are a rich source of scene information. We aim to develop new methods that use these data to infer scene geometry, reflectance, material properties, and more. As such, we believe extensions of the proposed approach could have a broad array of applications in 3D computer vision, remote sensing, and biomedical imaging. Due to the long acquisition times required for multi-view transient videography, our method is currently limited to static scenes. Acquisition times could potentially be reduced by simultaneous multi-view captures with emerging time stamping SPAD arrays, which may allow capturing transient effects within dynamic scenes. We look forward to new advances based on multi-viewpoint transient videography.

**Fig. 7:** Visualization of the direct–global separation on the *David* scene. The visualization of global illumination captures effects such as the interreflections on the wall or subsurface scattering in the candles.

Extensions of the proposed approach could have a broad array of applications in 3D computer vision, remote sensing, and biomedical imaging. Due to the long acquisition times required for multi-view transient videography, our method is currently limited to static scenes. Acquisition times could potentially be reduced by simultaneous multi-view captures with emerging time stamping SPAD arrays, which may allow capturing transient effects within dynamic scenes. We look forward to new advances based on multi-viewpoint transient videography.

## S1 Implementation details

### S1.1 Proposed Method

The proposed method builds on NerfAcc’s [4] Instant-NGP implementation using an occupancy grid. We use a batch size of  $2^{17}$  samples for the simulated dataset and  $2^{16}$  samples for the captured dataset, where each batch aggregates samples along all rendered rays. For the occupancy grid we use a threshold of  $10^{-2}$  for binarization. We preprocess the data by dividing by the factor given in Table S1 and Table S2, where these parameters are roughly the 90th percentile value of the transient video rendered or captured for a centered view of the scene. We then tonemap the data by clipping the transient video between the values of 0 and 1 and applying a gamma correction with  $\gamma = 5$  for simulated data and  $\gamma = 2$  for captured data. Overall, these parameters are selected to balance contrast and detail in the rendered transient videos.

### S1.2 Transient NeRF

We implement Transient NeRF using the NerfAcc framework based on the description provided by the Malik et al. [5], and the training procedure follows that of the proposed method, including using 500k iterations for optimization on simulated data and 1M iterations for optimization on captured data. Following the authors’ description of the method, no proprocessing (i.e., gamma correction) of the data is applied. Following Malik et al. [5] we use the Mitsuba-based temporal filter for the simulated dataset.

We also modify the rendering procedure to account for the non-coaxial illumination and imaging setup used in our simulations. Specifically, during the ray marching procedure we (1) calculate the path length to each sample along the camera ray, (2) calculate the distance from that point to the point light source (ignoring occlusions), and (3) assign the corresponding time-resolved radiance to a transient bin that accounts for the round trip distance from the light source to the sample and to the camera.

---

### S1.3 K-Planes

We follow the original K-Planes [2] implementation, training each scene with a ray batch size of 4096. Each scene is trained for a total of 300,000 iterations; this number is obtained by scaling the training hyper-parameters from the original K-Planes implementation based on number of views and sequence length of our data. Due to the limited expressivity of the K-Planes architecture, we crop simulated and captured datasets in the time dimension. This prevents the architecture from allocating capacity to fit parts of the transient where nearly no photons are detected. For the simulated results, we crop the transients by identifying, across all viewpoints, the shortest contiguous time sequence in which a photon is detected in every transient video frame. We follow the original K-Planes implementation and set the spatial resolution of the feature grid to 64 and the temporal resolution to 25. For captured results, we train on the first 3000 time bins of each transient video. Since captured scenes are typically longer in time than simulated scenes, we increase the temporal resolution of the feature grid to 100.

### S1.4 Direct–Global Separation

Our method can be used for 3D visualization of direct and global components of light transport. To separate light into direct and global components, we use the following procedure. First, we pre-process the captured transient data to separate direct and global components by fitting a Gaussian mixture model (with 5 components) to the 1D temporal waveform of each transient video pixel for all viewpoints. We use the implementation of `scikit-learn` [6] to fit the mixture. To identify the direct component, we perform a normalized cross-correlation between the fitted Gaussian mixture and the calibrated response of picosecond laser and SPAD to a direct reflection from a diffuse target. We identify if the maximum value of the normalized cross-correlation exceeds a threshold and, if so, the direct component is taken to be all Gaussians whose mean is less than the argmax of the normalized cross-correlation. Then, we set the indirect component to the remaining Gaussians. Alternatively, if no direct component is detected (i.e., the normalized cross-correlation does not exceed the threshold), the indirect component is taken to be the entire mixture of Gaussians. We set the threshold to 0.5 and find that this provides adequate selectivity for the direct component. Finally, we train separate instances of our model on the direct and global components, enabling synthesis of direct and global transient videos from novel viewpoints (see supplemental video).

## S2 Evaluation metrics

### S2.1 Transient IoU

We introduce the transient intersection-over-union (IoU) metric. This metric calculates the overlap between two time-resolved waveforms (i.e., transients) and

hence provides a measure of their similarity. Here, the intersection corresponds to the overlapping area of the two transients, and the union is the area when the greater of the transients at each time bin is considered. We assume that both transients are non-negative. The IoU is then calculated as the ratio of the intersection to the union of the histograms. Mathematically, it can be expressed as:

$$\text{IoU}(\tau_1, \tau_2) = \frac{\sum_n \min(\tau_1[n], \tau_2[n])}{\sum_n \max(\tau_1[n], \tau_2[n])}, \quad (\text{S1})$$

where  $\tau_1, \tau_2$  are the transients being compared. The IoU metric ranges from 0 to 1, with a value of 1 indicating perfect overlap and complete similarity between the two histograms, while a value of 0 indicates no overlap and complete dissimilarity.

## S2.2 PSNR, LPIPS and SSIM

To calculate the image metrics, we need a 2D representation of our transient. To arrive at this representation, we take the integrated transient output for each method (over the time dimension), this gives a raw image, which is then scaled and clipped between 0 and 1. After that the images are gamma corrected with  $\gamma = 2.2$ . These images are then compared for PSNR, LPIPS and SSIM. The scales are shared between all methods and are fixed per dataset.

### S3 Dataset

The exact details of all the simulated and captured datasets can be found in Table S1 and Table S2 respectively.

**Table S1:** Descriptions of simulated scenes. All scenes have a test set of 60 test images.

	scene description	training views	azimuth span	elevation span	bin width	normalization scale
Cornell box	A light source from the top illuminates two boxes, highlighting interreflections.	93	180°	45°	0.1	43
Peppers	A point light source from the top illuminates a glass ball and two peppers, red and green. The scene highlights refractions.	93	45°	30°	0.02	5
Pots	A point light source from the top illuminates a ficus and stacked pots, which are in front of a glass pillar. This scene highlights interreflections, refractions and shows more complicated geometry.	93	90°	30°	0.02	500
Caustics	A volume filled with smoke contains a point light source and a glass ball. The glass ball focuses the light which leaves the point source.	45	45°	15°	0.05	20

**Table S2:** Descriptions of the captured scenes. All scenes have a calibrated bin width of 0.0105 m and span 15 degrees in elevation angle.

	scene description	training views	test views	azimuth span	normalization scale	exposure time (s)
Coke bottle	A collimated beam enters a coke bottle, it gets focused at the cap.	36	9	360°	1000	2000
Kennedy	A points source illuminates a brass Kennedy statue, we also witness interreflections in a mirror in the scene.	60	15	150°	400	1000
David	A point source illuminates a statue of David and two candles from the side.	60	15	150°	6000	1000
Mirror	A fish tank filled with water and a bit of milk. A collimated beam enters the tank and gets reflected on to a diffuser by a mirror.	36	9	90°	1500	2000
Diffraction	A fish tank filled with water and milk. A collimated beam enters the tank and gets diffracted by a grating.	39	9	90°	500	2000

## S4 Additional Results

### S4.1 Simulated Results

We provide additional results on the simulated dataset (see Fig. S1) and report metrics for each scene (Tables S3, S4, S5, S6). We observe similar trends as in the main text; the proposed method without propagation delay modeling and K-Planes [2] fail to reconstruct transients with correct timing. In scenes with more inter-reflections, these methods fail entirely. T-NeRF [5] fails to reconstruct global illumination components. While the proposed method without propagation delay yields strong results across the image quality metrics, we note that it is only the *integrated images* that appear correct; the transient has incorrect time shifts, which results in a lower transient IoU score for that method.

**Table S3:** PSNR (dB) results on the simulated scenes.

	Cornell	box	peppers	pots	smoke	mean ↑
T-NeRF	21.471	27.119	28.916	27.892	26.349	
K-Planes	13.768	18.391	18.728	31.317	20.551	
w/o prop. delay	13.271	28.080	29.448	40.367	27.791	
proposed	33.746	28.634	32.695	36.783	32.965	

**Table S4:** LPIPS results on the simulated scenes.

	Cornell	box	peppers	pots	smoke	mean ↓
T-NeRF	0.361	0.334	0.320	0.337	0.338	
K-Planes	0.525	0.298	0.707	0.192	0.431	
w/o prop. delay	0.495	0.321	0.345	0.175	0.334	
proposed	0.211	0.247	0.292	0.239	0.247	

**Table S5:** SSIM results on the simulated scenes.

**Table S6:** Transient IoU results on the simulated scenes.

	<i>Cornell box</i>	<i>peppers</i>	<i>pots</i>	<i>smoke</i>	mean ↑
T-NeRF	0.781	0.712	0.798	0.626	0.729
K-Planes	0.335	0.346	0.295	0.455	0.358
w/o prop. delay	0.185	0.360	0.456	0.472	0.368
proposed	0.915	0.722	0.858	0.824	0.830

## S4.2 Captured Results

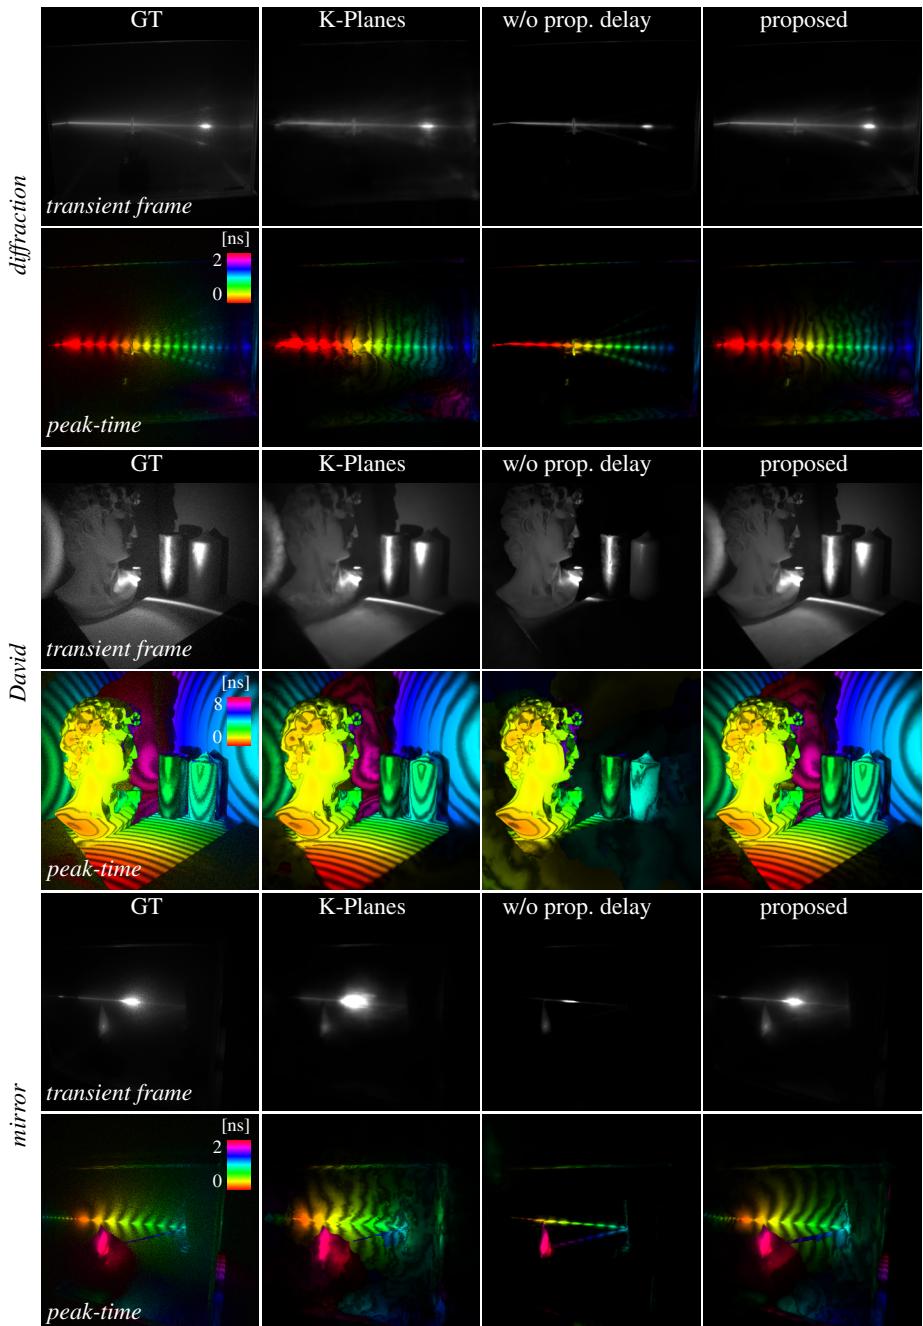

We provide additional results on the captured dataset (see Figs. S2 and S3) and report metrics for each scene (Tables S7, S9, S8, S10). Again, we observe similar trends to the main text.

**Table S7:** PSNR (dB) results on the captured scenes.

	<i>Coke bottle</i>	<i>Kennedy</i>	<i>David</i>	<i>mirror</i>	<i>diffraction</i>	mean ↑
K-Planes	20.979	20.690	29.810	27.060	22.035	24.635
w/o prop. delay	17.050	14.002	18.882	19.614	16.043	17.118
proposed	22.429	21.607	30.388	27.598	22.722	24.949

**Table S8:** SSIM results on the captured scenes.

	<i>Coke</i>	<i>bottle</i>	<i>Kennedy</i>	<i>David</i>	<i>mirror</i>	<i>diffraction</i>	mean ↓
K-Planes	0.519	0.561	0.433	0.511	0.559	0.506	
w/o prop. delay	0.504	0.526	0.506	0.531	0.580	0.529	
proposed	0.414	0.410	0.364	0.461	0.506	0.431	

**Fig. S2:** Additional captured results, transient frames, and peak-time visualizations.

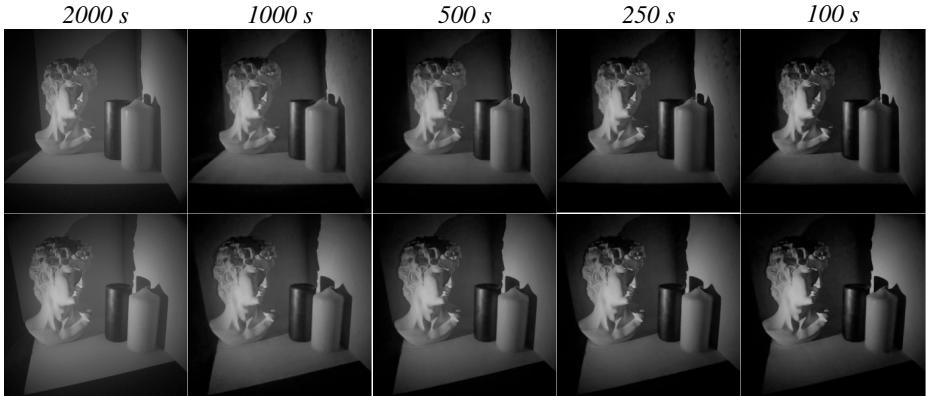

**Fig. S3:** Additional captured results, transient frames, and peak-time visualizations.

**Table S9:** LPIPS results on the captured scenes.

	<i>Coke bottle</i>	<i>Kennedy</i>	<i>David</i>	<i>mirror</i>	<i>diffraction</i>	mean ↑
K-Planes	0.430	0.654	0.764	0.598	0.525	0.612
w/o prop. delay	0.200	0.438	0.438	0.403	0.251	0.346
proposed	0.351	0.774	0.876	0.717	0.611	0.666

**Table S10:** Transient IoU results on the captured scenes.

	<i>Coke bottle</i>	<i>Kennedy</i>	<i>David</i>	<i>mirror</i>	<i>diffraction</i>	mean ↑
K-Planes	0.118	0.492	0.580	0.435	0.351	0.406
w/o prop. delay	0.002	0.359	0.336	0.052	0.119	0.174
proposed	0.298	0.574	0.607	0.460	0.399	0.468

**Fig. S4:** Integrated transient videos rendered from novel views trained using transients with different light levels on the *David* scene. The method is trained on different subsets of the photon counts collected within the indicated exposure times per each view; at low photon count settings, the method struggles to reconstruct darker regions due to the low signal-to-noise ratio.

**Table S11:** Reconstruction quality vs. exposure time for the *David* scene. We report image quality metrics and Transient IoU for the proposed method trained on transient videos captured with varying exposure times.

	PSNR ↑	LPIPS ↓	SSIM ↑	Transient IoU ↑
100s	24.030	0.391	0.683	0.512
250s	26.173	0.372	0.779	0.564
500s	27.971	0.355	0.848	0.578
1000s	30.388	0.364	0.876	0.607

### S4.3 Noise Analysis

We conduct an experiment involving variations in the exposure time, specifically, we train the proposed method using the photons captured within one-half, one-tenth, and one-quarter of the original exposure time. This translates to an exposure time of 500s, 250s, 100s respectively, per each transient video. As expected, the reconstruction quality degrades somewhat with decreasing photon counts for all metrics (see Tab. S11). While the method performs worse in darker regions (which have lower signal-to-noise ratio) as the exposure time decreases, the main scene details are still accurately reconstructed even at the lowest exposure setting.

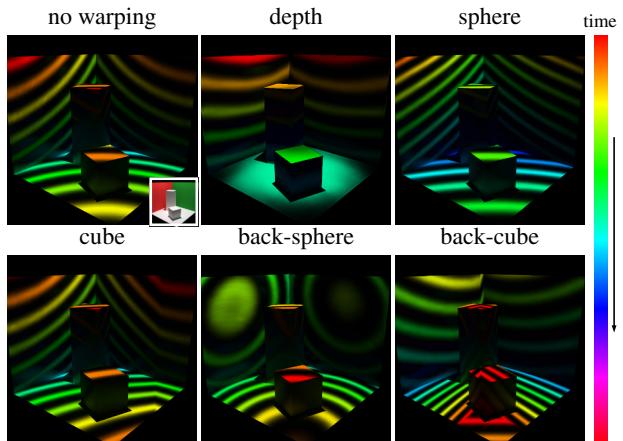

### S4.4 Time Warping

Our approach can be used to visualize light transport in different ways through time warping, which involves adding or removing time delays to the rendered

transients. Following Velten et. al [7] we perform depth-based time warping, which removes the propagation delay from the scene point to the camera. In the visualization with depth-based warping, points along each camera ray “light up” as soon as they intersect a wavefront of light; in other words, each camera ray is rendered in a different spacetime coordinate frame. To create this visualization, we calculate the propagation delay to each scene point using the expected ray termination distance [1], and we shift the rendered transient by the corresponding speed-of-light time delay. We compare transients rendered with and without depth-based warping in Fig. S5.

Our representation enables more general time warping techniques, wherein we shift the transients based on the distance to arbitrary reference surfaces (e.g., defined by a sphere, cube, etc.). We explore extensions to time warping and associated novel visualization techniques in Figure S5, specifically, we show sphere, cube, back-sphere and back-cube warpings for the *Cornell box* scene.

To perform the sphere warping each transient is shifted by the distance between the camera origin and a sphere that encapsulates the scene. Using the sphere surface as the spacetime reference frame reduces view-dependent changes in the appearance of the scene, especially as the scene-camera distance increases. Rather than shifting the transient by the distance between the camera origin

**Fig. S5:** Visualization of different methods for time warping.

and the sphere, we can instead shift by the distance between the camera origin and the second intersection with the sphere; we call this the back-sphere warping. This method for warping accentuates the curvature of propagating wavefronts. We can similarly visualize wavefronts using a spacetime reference frame corresponding to the surface of a cube that encapsulates the scene. Then, we can shift the transients by the distance from the camera center of projection to the near surface of the cube (cube warping) or the far surface of the cube (back-cube warping).

#### S4.5 Relativistic Rendering

To create the relativistic visualizations we reimplement the relativistic rendering procedures of Jarabo et al. [3]. We now explain how we implement the relativistic effects, shown in the main paper figures. Let the observer speed be given as  $v = \beta c$ , where  $c$  is the speed of light and  $\beta$  is a factor. Then we denote  $\gamma = \frac{1}{(1-\beta^2)^{1/2}}$ .

*Camera deformation.* This effect is caused by the Lorentz contraction; here the camera field of view changes based on the camera velocity. To implement the camera deformation we augment the camera’s field of view. Specifically let  $f_x, f_y$  be the focal lengths in the horizontal and vertical directions, then the new camera focal lengths are given as  $f'_x = \frac{f_x}{\gamma}$  and  $f'_y = \frac{f_y}{\gamma}$ .

*Relativistic aberration.* This operation warps the camera rays based on the camera velocity. Specifically, let also  $v$  be the camera ray vector and  $M$  the velocity vector of the observer. Then  $\theta$  is the angle between them, due to relativity this angle gets changed. In particular, the new angle is given through its cosine:

$$\cos(\theta') = \frac{\cos(\theta) - \beta}{1 - \beta \cos(\theta)}. \quad (\text{S2})$$

*Time dilation.* This operation shifts and stretches the transients in time. The exact equations for these warpings are provided by Jarabo et al. [3] (see their Eq. 3, and Eq. 11).

*Searchlight effect.* This operation applies a spatial modulation to the intensity of light based on the camera velocity. Let  $D = \gamma(1 + \beta \cos(\theta'))$ , where  $\theta'$  gives the warped rays’ angles for the image as described in the *Relativistic aberration* section. Then the radiance of the ray is scaled by the factor  $D^{-5}$  [3]. This results in increased brightness in the center of the image or the edges, depending on the direction of motion.

We do not implement Doppler shift [8] because the transient videos are captured using a narrowband pulsed laser (so no relative shift between wavelengths would be observed).
